

Image Fusion by a Hybrid Multiobjective Genetic Algorithm Technique

Jyoti S. Kulkarni

Abstract: Sensors used in image acquisition. This sensor technology is going on upgrading as per user need or as per need of an application. Multiple sensors collect the information of their respective wavelength band. But one sensor is not sufficient to acquire the complete information of one scene. To gain the overall data of one part, it becomes essential to cartel the images from multiple sources. This is achieved through merging. It is the method of merging the data from dissimilar input sources to create a more informative image compared with an image from a single input source. These are multisensor photos e.g. panchromatic and multispectral images. The first image offers spatial records whereas the lateral image offers spectral data. Through visible inspections, the panchromatic photo is clearer than a multispectral photo however the grey shade image is. Articles are greater clear however now not recognized whereas multispectral picture displays one of a kind shades however performing distortion. So comparing the characteristics of these two images, the resultant image is greater explanatory than these enter images. Fusion is done using different transform methods as well as the genetic algorithm. Comparing the results obtained by these methods, the output image by the genetic algorithm is clearer. The feature of the resultant image is verified through parameters such as root mean square error, peak signal to noise ratio, mutual information, and spatial frequency. In the subjective analysis, some transform techniques also giving exact fused images. The hybrid approach combines the transform technique and a genetic algorithm is used for image fusion. This is again compared with genetic algorithm results. The same performance parameters are used. And it is observed that the hybrid genetic algorithm is superior to the genetic algorithm. Here the only root means square error parameter is considered under the fitness function of the genetic algorithm so only this parameter is far better than the remaining parameters. If we consider all parameters in the fitness function of the genetic algorithm then all parameters using a hybrid genetic algorithm will give better performance. This method is called a hybrid multiobjective genetic algorithm.

Keywords: Genetic Algorithm, Hybrid Multiobjec Tive Genetic Algorithm, Image Fusion

I. INTRODUCTION

The fusion of images from the same source at a different time is called multitemporal image fusion. This type of image fusion is useful in change detection. The same material with different spectral phenomena gives the change in pixel value to find the changes.

Change detection useful for land use, urban growth, forest dynamics and disaster management, etc. Numbers of image fusion techniques are available [7]. The image fusion strategies are spatial area and a frequency domain. The spatial area image fusion makes use of the images as it is i.e. they straight operate on pixels. In the frequency domain, the transform is used before image fusion. Spatial domain image fusion methods are averaging method, Principal Component Analysis, IHS transform, High Pass Filtering, and Brovey Transform. The drawback of spatial domain fusion is spectral poverty. Because of this, the transform domain fusion method is chosen. The transform domain approach makes use of different transforms such as discrete cosine transform, discrete wavelet transform, and Kekre transform. Discrete Cosine Transform is the fast transform represented by a real and orthogonal matrix. Discrete Wavelet Transform uses a wavelet expansion function which gives the time-frequency localization and energy of the signal. Kekre transform is represented in the form of a generic matrix where needsdo not have the power of 2. In this transform, values above the diagonal are 1 and except below the diagonal line, lower diagonal values are zero. Among these, it is necessary to select the optimized technique or optimum fused image. As optimization is needed in the image fusion process, evolutionary algorithms can give the optimized output. The different evolutionary algorithms are Genetic Algorithm, Genetic Programming, Evolutionary programming, Learning Classifier System, Ant colony optimization, Particle swarm optimization, Artificial Bee Colony, Evolution strategy, Swarm intelligence, Tabu Search, Cuckoo Search, etc. A genetic algorithm is a method for solving constrained and unconstrained optimization problems based on a natural selection process that mimics biological evolution. The genetic algorithm gives the solution for the optimization of hard problems quickly, reliably, and accurately. Each solution is separate and the set is the population. The objective characteristic rating is fitness. Higher objective function value solutions are replicated to allow more searches. Local search stages are mutation and crossover. Optimization proceeds in a sequence of generations. Two solutions that can be blended to create a new one is crossover. A heuristic approach for problem-solving is a class of computational problems by combining user-given heuristics towards a more efficient procedure. Fusion is done using these transform methods as well as the genetic algorithm. Comparing the results obtained by these methods, it is concluded that the output produced by the genetic algorithm is clearer. The superiority of the fused image is verified using performance parameters. In the subjective analysis, some transform techniques also giving a better output [27].

Then hybrid method i.e. combination of the transform technique and genetic algorithm can be used for image fusion. This is again compared with genetic algorithm results for the same performance parameters. And it is observed that the hybrid genetic algorithm is superior to the genetic algorithm [30]. Here the only root means square error parameter is considered under the fitness function of the genetic algorithm so only this parameter is way better than the remaining parameters. When only one objective is involved in the problem, it is called single-objective optimization, but in most applications, more than one objective is required to be optimized. This is multi-objective optimization. The objective function values are compared to find the superiority of a solution in the single-objective optimization problem whereas, in the multi-objective optimization problem, the quality of the solution is determined by the dominance. As it may not be suitable to examine a fused image based on a single metric, the excellence of a fused image should be estimated by combining two or more metrics in a manner that overwhelms the limitations of the individual metric. In this, a set of solutions is acquired and the preferred solution is selected according to advanced level information. The set of all solutions that are non-dominated by any other solution is called the Pareto optimal set. The values of objective functions related to each solution of a Pareto optimal set is called Pareto front. By using the weighted sum method, the multi objectives are transformed into a single objective function [4, 15]. Here, minimization problems with only two objectives are investigated. As discussed previously, in single objective method, the function used is RMSE. When the RMSE value is small, it indicates that the contents from input images are transferred into the fused image. Anyone parameter among the performance parameters SF, MI, IQI, and AG, one can be added with RMSE in multiobjective function. Here SF is considered, as the spatial frequency gives the object's shape and size information. The performance of this method is observed by using different performance parameters. This paper is organized into six sections. An introduction is the first section of the paper. After this, the next section will give knowledge about genetic algorithm-based image fusion. Then, the fusion technique using a hybrid genetic algorithm is explained. The proposed technique and also the entire process are presented in the next section. Experimental results on three data sets are illustrated in the results and discussions part. Finally, conclusions are presented in the last section.

II. IMAGE FUSION USING GENETIC ALGORITHM

Simple GA works under the basic three operations like selection, genetic operation, and replacement. A Group of chromosomes can form a population that supplies the range of solutions. Initially, the population is chosen randomly and also the fitness of this solution is calculated using a fitness function. The fitter solution has more possibility to require a possibility in the second generation. Likewise, parents are selected in the selection step. Then crossover, as well as mutation operations, is performed on selected parents. The offsprings are generated in this step. The parent i. e. old population is replaced by offspring [1, 3, 5]. Image fusion can be done by searching appropriate block sizes from input images through genetic search and then fusing these clearer blocks [2]. The genetic algorithm is also useful in image denoising. This is the preprocessing method for image fusion

to remove the noise from input images [8]. In remote sensing applications, a large number of filters is required to filter the data. The selection of filters is most important to achieve the required data information. This filter selection can be done by using a genetic algorithm that is further used for optimal feature selection [9]. It is also possible to retrieve the image information using color features and texture features from the fused image using a genetic algorithm [13,16]. A genetic algorithm is an unbiased optimization method to find the solution automatically. This increases the optimality with an increase in the generation or up to termination [14]. The genetic algorithm is used for image fusion. In this, two images are selected from the dataset to perform image fusion. In a genetic algorithm, create a preliminary population. This is created randomly with factors as size and number of bits. Population size is the number of chromosomes and the size of the chromosome given by the number of bits. For two input images, two populations are produced. The weight for the input image is nothing but the chromosome from the population is multiplied with the input image. These two new images are used for fusion. The fitness function is calculated for the fused image, will provide the fitness cost of every population. The same process is repeated for all populations. Next to the termination, the quantity of fitness values is the same as the population. Then the mediocre fitness is calculated. These fitness values are sorted in up order. Here, the first value is the best cost of the fitness function and the last value is the worst cost. For the probability of selection, roulette wheel selection can be used for the selection of parents. Then, with the help of crossover probability, two offsprings can be formed using a single point or double point crossover. And with the mutation probability, two offsprings are mutated and resulting chromosomes are inserted in the new population [27].

III. IMAGE FUSION USING HYBRID GENETIC ALGORITHM

In pixel-level genetic algorithm-based image fusion, the input images are used by a genetic search to find an optimum weight for each input image. This is basic-level image fusion using a genetic algorithm. To increase the quality of a fused image or for more optimization, the input image can be transformed by using any transform method before applying to a genetic search [5]. Liang et al., 2011, proposed image fusion under data assimilation. Through the model operator, a prediction image is the fused image after applying transform on input images. Through the observation operator, the observation image is the color composite of the image found by using HIS fusion. Now, these two images are used by the genetic algorithm to find an optimized image [6]. Image fusion using a hybrid genetic algorithm is the modification in the previous method which will give the improved result. The hybrid method can be formed by combining the spatial frequency which is working at the pixel level and the genetic algorithm which is working at the feature level. Inputs are splits into segments. The segment size is decided by the genetic algorithm. The corresponding blocks are compared to spatial frequency.

The higher spatial frequency block is selected for fusion [2,3]. Pixel level GA based, DWT based, and DWT-GA based fusion methods are explained in [5]. In the Pixel level GA-based method; the optimal weights are determined by the genetic search. The weight generated is less than 1 and then another weight is calculated such that the addition of two weights is 1. The fitness function used is the root means squared error equation. The fused image is achieved by the sum of the multiplication of the respective weight with the image at the pixel level. The DWT based method is the simple wavelet transform method using the maximum fusion rule. The DWT-GA based method is the combination of two techniques. The input images are decomposed into wavelet coefficients. These coefficients are the inputs to the genetic search to find optimal weight. The input image is multiplied by this weight to form the fused image [5]. Instead of DWT, discrete wave packet decomposition can also be used with a genetic algorithm for IF [15]. The hybrid genetic algorithm (HGA) is the combination of transform technique and genetic algorithm. Here, two input images i.e. panchromatic image and multispectral image are selected from the dataset for image fusion. Then, apply DCT on each band of input images separately. Now two transformed images are available. On these two input images, the genetic algorithm is applied. The result obtained from this method is improved compared with the previous method. Instead of DCT, other transform methods can also be used such as DWT and Kekre's WT [30].

IV. IMAGE FUSION USING HYBRID MULTIOBJECTIVE GENETIC ALGORITHM

A Pareto optimal set is a set of non-dominated solutions. Among the set of Pareto optimal solutions, there are variations in the value of objectives from one solution to other solution. It may happen that one solution is giving best value of one objective whereas other solution is giving worst for the same. For single solutions, pareto-optimal solution sets are frequently desired [4]. Pareto dominance and Pareto front used to find near optimal solution but simultaneous searching can be done by using multiobjective optimization to find optimal solution [14]. Thus multiobjective evolutionary algorithm is the best solution for multiple feature extraction. In this, for different features, different chromosomes with fitness function can be used [13]. The hybrid multiobjective genetic algorithm is the hybrid genetic algorithm for multiple parameters. The different performance parameters can be used in fitness function of GA.

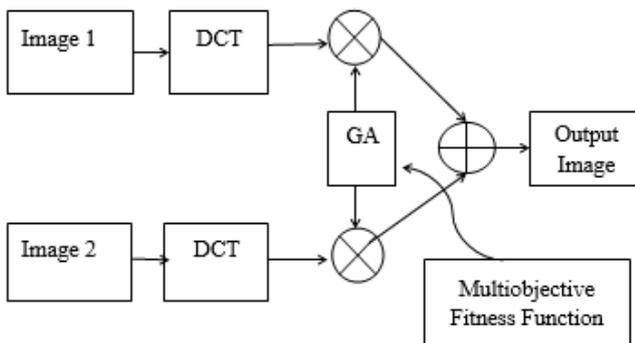

Fig. 1. Image Fusion using Hybrid Multiobjective Genetic Algorithm

The algorithm for image fusion by hybrid multiobjective genetic algorithm is as follows.

1. Selecting two images from given dataset.
2. Apply the required transform method on these input images separately. Two transformed images are available.
3. Generate preliminary population. It is created randomly with factors as size and number of bits. Initially take popsize as 50 and size of chromosomes as 16 bits.
4. Randomly generate the weight used for each image. Then multiply this weight with the input image. And fuse these images.
5. Apply the fitness function to the fused image. This contains the performance parameters as root mean square error, mutual information, and spatial frequency. This is the fitness of the population.
6. Repeat steps 3 to 5 for all populations. Finally, the numbers of fitness values are equivalent to the number of populations. The average fitness of these populations is calculated.
7. The values are sorted in descending order. As larger cost is the best cost, this is the first value whereas the worst cost is the last value.
8. The selection probability is calculated for the parent selection using the roulette wheel selection method.
9. Now by the crossover probability forming two offspring using double point crossover.
10. Calculate the mutation probability. The two offsprings are mutated and the resulting chromosome is placed in the new population.
11. The current population is replaced by the new one.
12. Steps 2 to 11 are repeated for all generations.

The fitness function for this algorithm is:

$$f(x) = \min \left\{ \left(\frac{1}{SF} \right), Rmse \right\} \quad (1)$$

Where Rmse is the root mean squared error and SF is spatial frequency. These parameters are defined as given below. Root mean square error: It is the amount of accuracy. It finds the change between the original and fused image. As a result, RMSE is calculated as

$$Rmse = \sqrt{\frac{1}{M \times N} \sum_{i=1}^M \sum_{j=1}^N (Im(i, j) - Imf(i, j))^2} \quad (2)$$

Where Im is the standard image, Imf is the fused image, MxN is the size of the image.

Spatial frequency: This provides the spatial information of an image concerning the high frequency and low -frequency domain. It is calculated as

$$SF = \sqrt{CF^2 + RF^2} \quad (3)$$

Where CF and RF are the column and row frequency of an image respectively.

V. RESULTS AND DISCUSSIONS

The acts of the image fusion technique are assessed by RMSE, Mutual Information, Image Quality Index, and Spatial frequency. Setting the genetic operators as per table 1, and observed the performance. The input images are used for testing and observed the output. The types of inputs are multisensor RGB and Gray images, multisensor medical images, and multifocus RGB images.

Image Fusion by a Hybrid Multiobjective Genetic Algorithm Technique

These images are taken from the standard dataset. This is assumed that images are properly registered. Simulation is carried out using the Image processing toolbox in Matlab on Intel (R) Celeron (R) 1.50 GHz CPU processor. Analysis of the output images is done in three steps: through visual inspection, through different performance parameters, and from histogram analysis.

Table 1 Genetic Operators

Operator	Value
Iterations	100
Chromosome size	50
Mutation rate	0.05
Bits in chromosome	8/16
Crossover type	Double point

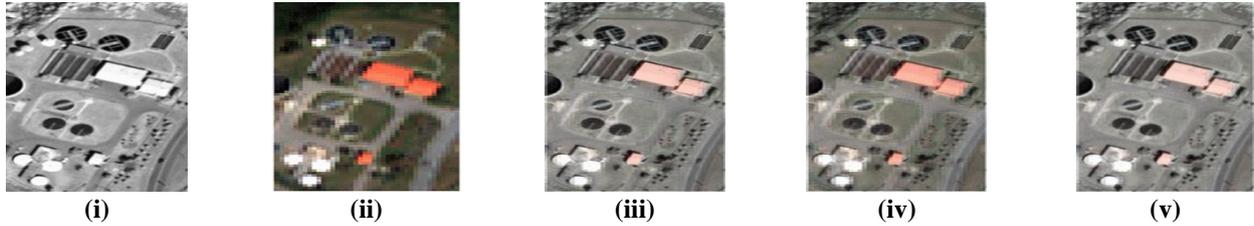

Fig. 2. Image group 1 (i) and (ii) are multisensor input images, (iii) to (v) are fused images due to Genetic Algorithm, Hybrid Genetic Algorithm and Hybrid Multiobjective Genetic Algorithm respectively.

Fig. 3. Image group 2 (i) and (ii) are multifocus input images, (iii) to (v) are fused images due to Genetic Algorithm, Hybrid Genetic Algorithm and Hybrid Multiobjective Genetic Algorithm respectively.

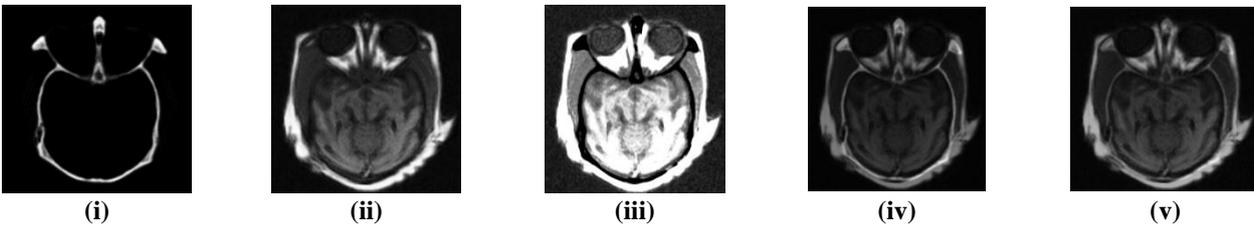

Fig. 4. Image group 3 (i) and (ii) are medical input images, (iii) to (v) are fused images due to Genetic Algorithm, Hybrid Genetic Algorithm, and Hybrid Multiobjective Genetic Algorithm respectively.

Table 2: Performance parameters of output image using GA, HGA, and HMOGA for different image groups

Quality Indices	Image group 1			Image group 2			Image group 3		
	GA	HGA	HMOGA	GA	HGA	HMOGA	GA	HGA	HMOGA
Mean	120.1	117.6	133.9	156.2	158.3	156.9	137.8	30.8	39.9
Entropy	7.22	7.24	7.22	7.59	7.48	7.40	5.06	5.88	5.99
Var	1656	1680	1796	5511	8306	4521	30958	1113	1646
Stddev	40.69	40.98	42.38	74.24	91.14	67.24	175.94	33.37	40.57
RMSE	37.64	25.50	39.70	7.64	5.60	9.57	36.88	23.42	38.42
PSNR	37.25	37.12	35.53	41.27	30.81	65.35	5.35	37.92	36.41
SF	18.79	18.72	21.17	43.60	64.83	14.94	50.47	9.41	10.15
MI	1.12	1.17	1.30	2.76	2.98	3.39	2.50	2.54	2.68
IQI	0.35	0.37	0.15	0.68	0.77	0.98	0.24	0.59	0.60
AG	76.07	74.45	88.41	110.52	143.62	50.77	97.84	37.90	43.65

The primary step of analysis is the visual inspection. Fig. 2 to 4 shows the input images and output images due to the above-described methods. Fig. 2(i) is the panchromatic and (ii) is the multispectral input. Comparing (iii) to (v), (iii) and (v) are almost the same whereas (iv) which is the output of HGA, is giving more spectral information. Fig. 3(i) and (ii) are multifocus images where the focus is on a different

part of the scene. Observing the output images, here also output due to HGA is superior to the rest of the methods. Medical input images are given in fig. 4(i) and (ii). In this test set, the output due to GA is clearer than HGA.

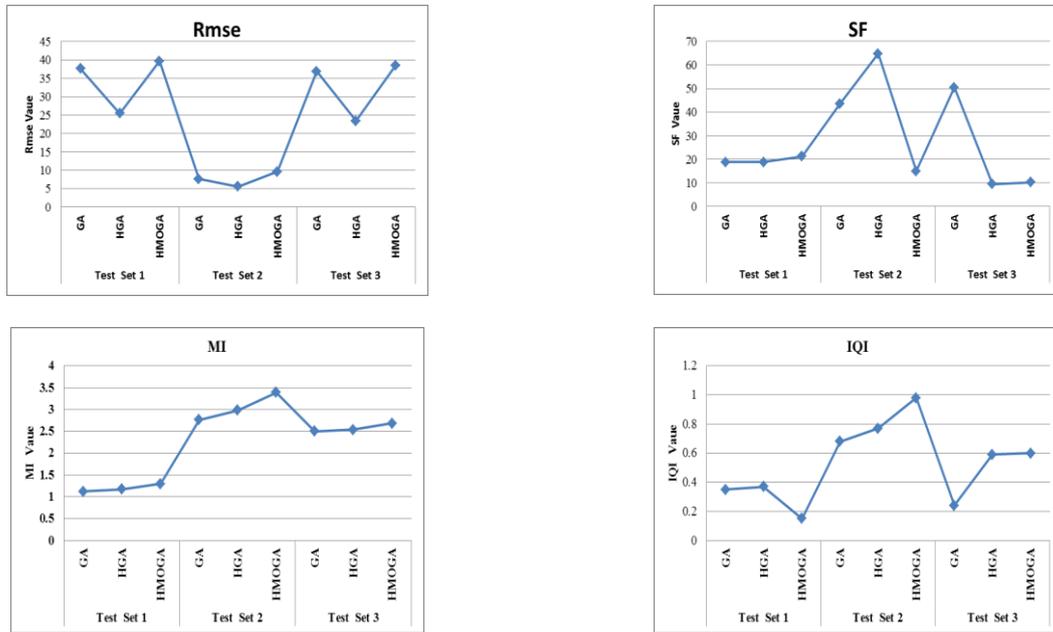

Fig. 5. Performance parameters of the fused image using Hybrid Multiobjective Genetic Algorithm

Another way of analysis of output generated by different methods is through performance parameters. Table 2 is the detailed representation of these parameters. Fig. 5 is the graphical representation of some parameters such as Rmse, SF, MI, and IQI. The rmse behavior in GA and HMOGA is

almost the same but in HGA, it is better than GA and HMOGA. But by observing the rest of the parameters i.e. SF, MI, and IQI, the performance of HMOGA is better than HGA which is better than GA.

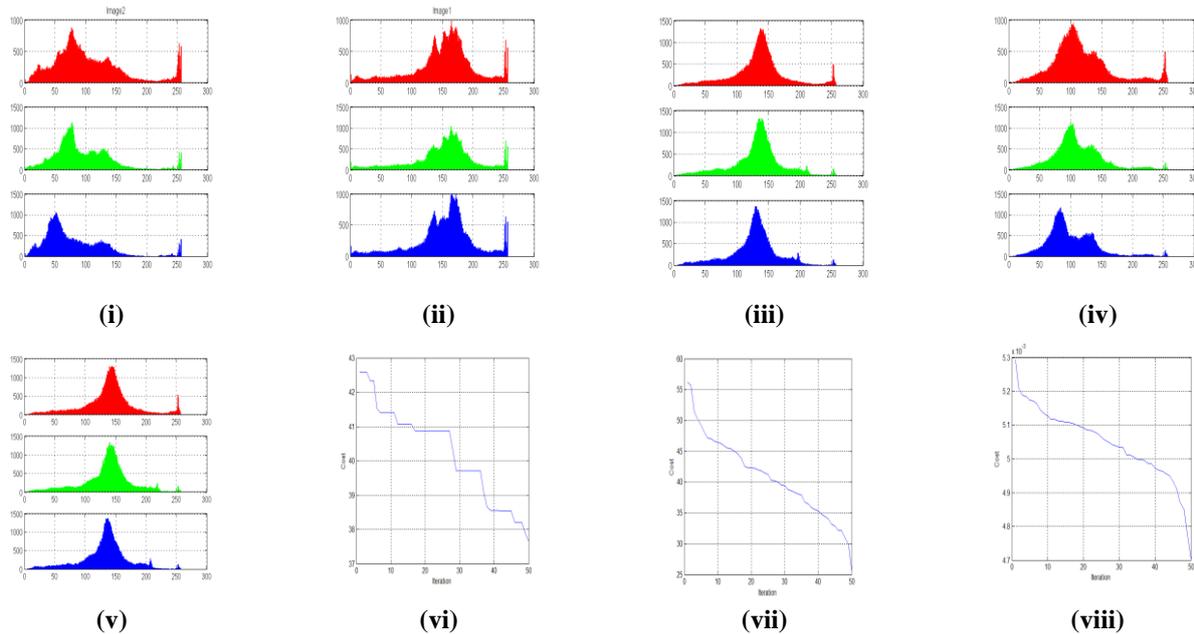

Fig. 6. (i) and (ii) are histogram representation of input images, (iii) to (v) are histogram representation of output images due to GA, HGA, HMOGA respectively, (vi) to (viii) are fitness function behavior in GA, HGA, HMOGA respectively.

The third method of analysis is through histogram representation. The histogram gives the statistics of the total number of pixels in a specific value region. The above histogram is of multisensor satellite images where Fig. 6(i) is the histogram of panchromatic and (ii) is of multispectral. Thus comparing the histograms of output images generated due to GA, HGA, and HMOGA given in Fig 6(iii), (iv), and (v) respectively, the spectrum band in (iv) is good as compared with the remaining pictures.

VI. CONCLUSIONS

Image fusion is a powerful technique to extract important data from input images. However, image fusion using existing methods such as spatial domain or transform domain were not giving optimized results.

Optimization can be accomplished through evolutionary approaches. A genetic algorithm is one of the important tools. This is used with different transform techniques for image fusion. As the genetic algorithm is well proven for the optimized result, it is combined with transform techniques to increase the performance of the method. This is a hybrid genetic algorithm method for image fusion. This is giving optimized results for a single performance parameter. Optimization of multiple performance parameters is done by using a hybrid multiobjective genetic algorithm. In this, multiple parameters such as root mean square error, spatial frequency, mutual information, and image quality index are optimized. The fitness function is designed using these parameters. And from table 2, our proposed method is giving better results.
